

# Lecture 17 - Objects and State

---

## Motivation and History

---

State, Collections of data.

Separation of Data from Operations on data.

We could store data in lists

```
1: kirk = ["James Kirk", 34, "Captain", 2265]
2: spock = ["Spock", 35, "Science Officer", 2254]
3: mccoy = ["Leonard McCoy", "Chief Medical Officer", 2266]
4:
5: print ( kirk[1] )
6: print ( spock[1] )
7: print ( mccoy[1] )
```

## Python's Implementation is Objects

---

Objects are created as a package that defines the layout and names for data and combines that with functions that operate on the data. These functions are called "methods".

Create a Class:

```
1: class Dog:
2:     pass
```

Initialization is important - so with a class we have a special function called `__init__` that setups the data and initializes it.

```
1: class Dog:
2:     def __init__(self, name, age):
3:         self.name = name
4:         self.age = age
5:         self.food = ""
```

This introduces the term `self` - in other languages it is often called `this`. `self` refers to the set of data that this class is going to work on. In the constructor, the special function called `__init__`, `self.name` creates a variable called `name` that is tied to the instance data for this class.

By doing the `__init__` in this way we require that creating a `Dog` means that you must pass 2 values, then `name` and the `age`.

```
1: class Dog:
2:     def __init__(self, name, age):
3:         self.name = name
4:         self.age = age
5:         self.food = ""
6:
7: spot = Dog('Spot',2)
8: kitty = Dog('Kitty',5)
```

And...

Access some values in the data.

```
1: class Dog:
2:     def __init__(self, name, age):
3:         self.name = name
4:         self.age = age
5:         self.food = ""
6:
7: spot = Dog('Spot',2)
8: kitty = Dog('Kitty',5)
9:
10: print ( spot )
```

We can create functions that change parts of the class data.

```
1: class Dog:
2:     def __init__(self, name, age):
3:         self.name = name
4:         self.age = age
5:         self.food = ""
6:
7:     def setFood(self, food):
8:         self.food = food
9:
10:    def getName(self):
11:        return self.name
```

```
12:
13: spot = Dog('Spot',2)
14: kitty = Dog('Kitty',5)
15:
16: spot.setFood ( "Kibbles" )
17: kitty.setFood ( "Purena Dog Chow" )
18:
19: print ( "{}'s favorite food is {}".format(spot.name, spot.food) )
```

You can compare to see if they are equal.

```
1: class Dog:
2:     def __init__(self, name, age):
3:         self.name = name
4:         self.age = age
5:         self.food = ""
6:
7:     def setFood(self, food):
8:         self.food = food
9:
10:    def getFood(self):
11:        return self.food
12:
13:    def getName(self):
14:        return self.name
15:
16:
17: spot = Dog('Spot',2)
18: kitty = Dog('Kitty',5)
19:
20: print ( "are they the same? {}".format( spot == kitty ) )
```

We can put the format of name/age into the class itself.

```
1: class Dog:
2:     def __init__(self, name, age):
3:         self.name = name
4:         self.age = age
5:         self.food = ""
6:
7:     def setFood(self, food):
8:         self.food = food
9:
10:    def getFood(self):
11:        return self.food
12:
```

```
13:     def getName(self):
14:         return self.name
15:
16:     def desc(self):
17:         return "{} is {} years old.".format(self.name, self.age)
18:
19: spot = Dog('Spot',2)
20: kitty = Dog('Kitty',5)
21:
22: print ( kitty.desc() )
```

We control how the values are changed inside the class.

```
1: class Dog:
2:     def __init__(self, name, age):
3:         self.name = name
4:         self.age = age
5:
6:     def setFood(self, food):
7:         self.food = food
8:
9:     def getFood(self):
10:        return self.food
11:
12:     def birthDay(self):
13:         self.age = self.age + 1
14:
15:     def getAge(self):
16:        return self.age
```
